## 5 **Executive Summary**

6 A method for solar forecasting using cloud motion vectors (CMV) from satellite imagery with the  
7 ability to characterize forecast uncertainty has been developed. On average, the root mean square error  
8 (RMSE) for CMV forecast increases with increasing forecast horizon and becomes larger than the North  
9 American Model (NAM, a numerical weather prediction model) forecast error at between 6 hours and 1  
10 day. Consequently, satellite CMV forecasts are superior for short time horizons and they are currently  
11 used as the model of choice in SolarAnywhere forecasts up to a 6 hour horizon. However, the forecast  
12 horizon at which the ‘crossover’ between CMV and NAM occurs is dynamic (as short as 2 hours) and  
13 could be adjusted if the CMV forecast certainty was known at forecast issue time. The RMSE of CMV  
14 forecasts was most related to satellite image entropy and uniformity. The relative performance (RP), i.e.  
15 the ratio of the errors of NAM and satellite CMV forecast is also analyzed. The average rRMSE of  
16 predicting RP is shown to be about 30% for two different modeling techniques. The models and metrics  
17 developed in this project can be applied to choose the optimal forecast model and reduce solar forecast  
18 errors especially for hour-ahead forecasts. An operational CMV forecast can be produced with a 25  
19 minute latency.

## 20 **1. Introduction**

21 Hours-ahead solar forecasting is important for grid operators to manage intra-day solar variability  
22 through procurement of reserves and operation of energy markets. As Geostationary Operational  
23 Environmental Satellite (GOES-15) was deployed last year and the more advanced GOES-R will be  
24 launched in 2017, the ability of solar forecasting using satellite imagery is expected to improve and to be  
25 widely used by forecast providers.

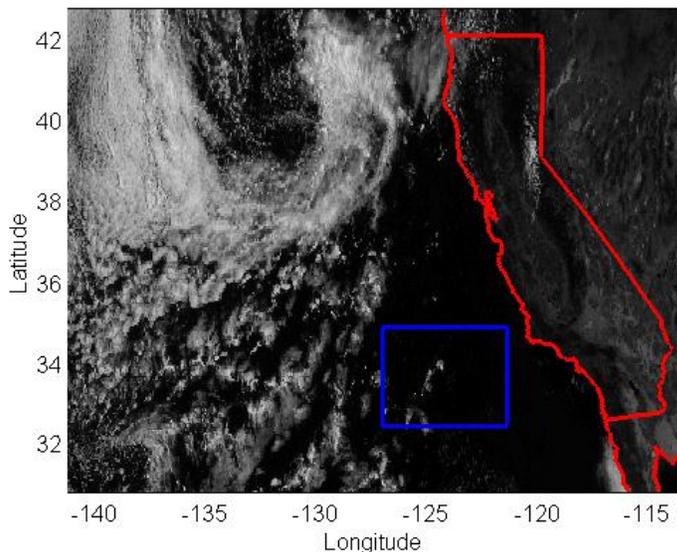

26 In this study, a technique for solar forecasting using satellite imagery with the ability to characterize  
27 and predict forecast error is presented. Many forecast techniques have been developed for solar  
28 irradiance using satellite imagery and Numerical Weather Prediction (NWP) (e.g. Hammer et al, 2000,  
29 Perez et al., 2010, 2011, Marquez et al., 2012). Perez et al (2010) showed that the satellite cloud motion-  
30 based forecasts improve upon NWP forecasts up to forecast horizons of 4-5 hours on average over the  
31 United States. For operational forecasting, however, the relative skill of different forecasts depends on  
32 meteorological conditions. The motivation of this study is to determine this “cross-over time” under  
33 different conditions and determine parameters (cloud cover fraction, cloud speed, etc.) that are good  
34 predictors for this cross-over time.

35 For NWP, good predictors of solar irradiance forecast error are clear sky index and solar zenith angle  
36 (Lorenz et al., 2009, Mathiesen and Kleissl, 2011). For satellite forecasts no published results on  
37 predictors of error exist. Knowledge of the cross-over time and determining parameters will allow the  
38 composition of a forecast across all time horizons, which is based on optimal combinations of inputs  
39 from different models. For example, a satellite model would be chosen as the forecast if it had been  
40 determined to be most accurate for frontal passages with homogeneous cloud cover and persistent  
41 cloud motion. More accurate and certain solar forecasts would facilitate more economical high solar  
42 penetration on the electric grid. In section 2, we describe the data set in this study. In section 3, the  
43 cloud motion vector method is introduced (3.1) and characteristic image features are defined (3.2). Also,  
44 multivariate linear regression and analog models are described. In section 4, overall NWP and CMV  
45 model performance is quantified (4.1) and then CMV errors are related to satellite image features  
46 qualitatively (4.2) and through linear regression models (4.3). Finally, section 4.4 analyzes the  
47 predictability of the relative performance of NWP and CMV forecasts using linear regression and analog  
48 methods. Conclusion are presented in section 5.

## 49 2. Data

### 50 2.1 Goes-15 Imager data

51 The Geostationary Operational Environmental Satellite-15 (GOES-15) Multispectral Imager  
52 satellite dataset from April 24<sup>th</sup> to May24<sup>th</sup> is used. GOES-15 generates a full disk image every 15 minutes  
53 with a spatial resolution of 1km and 4km for the visible and infrared bands, respectively. All of our  
54 results are presented at 4 km resolution. The domain of interest covers an open ocean region with an  
55 approximate size of 2000 km x 2000 km from 32°22' to 34°31' N and from 122°62' to 127°62' W (Fig  
56 1). Open ocean area is selected to avoid complex terrain effects that introduce stationary (mountain)  
57 clouds and high spatial variability in satellite measured reflectivity. GOES-15 images starting at 1645 and  
58 1700 UTC (09 PST) are used to determine cloud speed and the 1700 UTC cloud transmission image is  
59 advected with hourly time steps out to a forecast horizon of 6 hours.

**Figure 1.** GOES-15 visible channel image that shows the region of interest (blue) with the coast and California state lines (red).

## 60 2.2 CLAVR-x

61 The GOES-15 data is processed with the CLAVR-x algorithm developed by the GOES-R Advanced  
62 Baseline Imager (ABI) Cloud Algorithm Working Group (AWG) to provide cloud-related information.  
63 CLAVR-x generates cloud masks and classifies clouds into different types such as water, supercooled  
64 water, mixed phase, cirrus, opaque ice, etc (Pavolonis et al 2004, 2005). Among over thirty variables,  
65 cloud transmission and cloud mask with 4 km spatial resolution from the CLAVR-x are used. Assuming  
66 the atmosphere without clouds is transparent to the global horizontal irradiance (GHI), cloud  
67 transmission can be approximated as the clear sky index defined as

$$kt = \frac{GHI_{measured}}{GHI_{clear\ sky}}, \quad (1)$$

68 where  $GHI_{clear\ sky}$  is computed using a clear sky model that depends on location, time, elevation, and  
69 Linke turbidity (Ineichen and Perez, 2002). Since the spatial resolution and coordinate system is different  
70 between GOES-15 and NAM data. GOES-15 data is up-scaled and collocated with the NAM by simple  
71 averaging and linear interpolation.  
72

## 73 2.3 North American Mesoscale Model (NAM)

74 The total downward short wave radiation (GHI) from the NAM forecast is published by the  
75 National Oceanic and Atmospheric Administration's (NOAA) NCEP with a 12 km x 12 km grid spanning  
76 the continental United States (CONUS). Forecasts published at 12 UTC (shortly before sunrise at the  
77 region of interest) with hourly time steps out to 36 hours are used. Forecast  $kt$  is computed as in Eq. (1).  
78 Since satellite forecast issue time is 1700 UTC (Section 2.1), the sixth hour of the NAM forecast is  
79 compared to the first hour of satellite forecast and so on. Since the NAM forecast error varies only  
80 weakly in time for the first 24 hours (Perez et al., 2009), the difference in forecast horizon is not  
81 expected to impact the results.

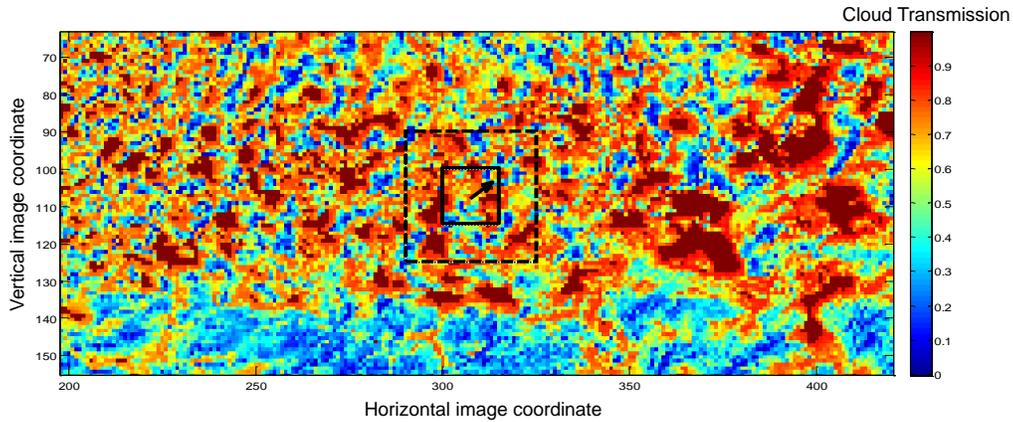

## 82 3. Methods

### 83 3.1 Cloud Motion Vectors Forecast

84 Atmospheric motion vectors (AMV) have been derived from geostationary satellites since the  
85 1960s (Fujita 1968) and different tracers and meteorological scales have been selected to derive AMV. In  
86 this paper, the cloud transmission or  $kt$  is used as a tracer. The cross-correlation method (CCM) and two  
87 consecutive (15 min apart)  $kt$  images are utilized to derive cloud motion vectors (CMVs). A 15 x 15 pixels  
88 (60 x 60 km) target box is used to cross-correlate within a 100 x 100 km search box (Fig. 2). This limits  
89 the maximum detectable velocity to 200 km h<sup>-1</sup>. To increase the computational efficiency, CCM only  
90 computed at 12 km resolution (every 3 pixels).

91 Assuming  $kt$  and CMVs remain constant over the forecast horizon, computed pixel-by-pixel  
92 CMVs are used to advect the  $kt$  pixels to each forecast horizon (Fig. 2). Nearest neighborhood  
93 interpolation is applied on sections of the forecast  $kt$  image where gaps and overlapping pixels are  
94 introduced by converging and diverging flow.

95 Two quality control procedures are applied. First, CMVs in cloud-free regions (as per the CLAVR-  
 96 x cloud mask) are removed. Second, AMVs that significantly differ from the neighboring vectors are  
 97 replaced using a median filter technique. These vectors might represent errors in the cross-correlation  
 98 algorithm or (less likely) depict actual local (microscale) motion associated with convective clouds  
 99 (Mecikalski 2002; Rabin et al. 2004). The objective is to estimate hours-ahead cloud motion, therefore,  
 100 small scale convective (and short-lived) cloud motion (as considered for example in Nieman et al. (1997),  
 101 Velden et al. (1997, 1998)) is neglected here.

**Figure 2.** Illustration of CCM on an image of cloud transmission (4 km resolution) at 10 PST on 7<sup>th</sup> June, 2012. A 60 x 60 km pixels target box (solid black line) is cross-correlated within a 100 x 100 km pixels search box (dash black line) from a cloud transmission image 15 minutes later (not shown here). A cloud motion vector is obtained for the center pixel of the target box.

### 102 3.2 Features

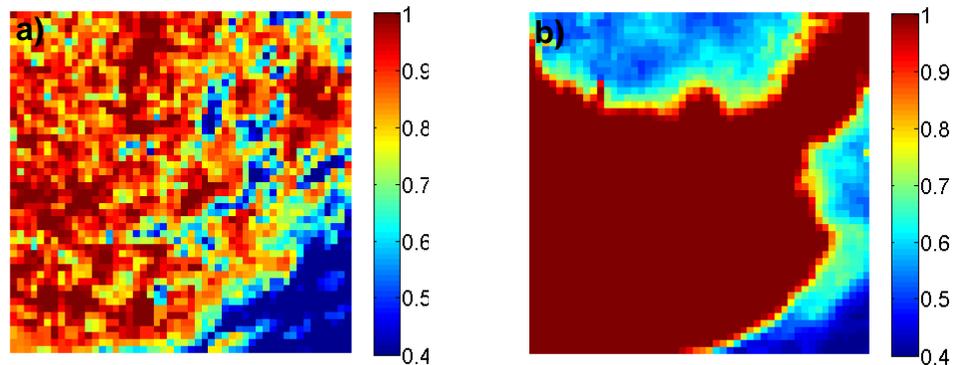

103 Seven different regional features (Table 1) extracted from the forecast kt maps are used to  
 104 characterize the CMV and NAM forecast error. For CMV forecast, spatially averaged cloud speed, kt  
 105 (AVGKT), correlation coefficient (CC) obtained as described in section 3.1, standard deviation of kt (std),  
 106 cloud fraction (Cf from CLAVR-x), entropy, and uniformity are computed over the domain (Fig. 1) to  
 107 represent the state of atmosphere (Fig. 3). All features are computed on the forecast kt image to  
 108 account for likely local conditions at the forecast valid time. For NAM, the same forecast features are  
 109 computed except cloud speed, std, and CC.

**Table 1.** Regional features that are extracted from the forecasted kt image and used as the predictors of CMV and NAM forecast error.

Regional Features	Formula	Description and Relevance
Cloud fraction (Cf)	$\frac{\# \text{ of cloudy pixels}}{\# \text{ of pixels}}$	An image with a very small or very large cloud fraction (clear or overcast) is easier to forecast
Cloud Speed	$\sum_{i=1}^n p(cs_i) cs_i$	$cs_i$ is the cloud speed of each pixel, $p$ is the probability of $cs_i$ , and $n$ is the number of pixels in an image. An image with higher cloud speed would be more difficult to forecast since error in cloud direction will cause clouds to diverge faster from

**Table 1.** Regional features that are extracted from the forecasted kt image and used as the predictors of CMV and NAM forecast error.

Regional Features	Formula	Description and Relevance
Correlation Coefficient (CC)	$\sum_{i=1}^n p(cc_i)cc_i$	Spatially averaged cross-correlation coefficient measuring the degree of correspondence between the 1645 and 1700 images that are used to determine CMVs (Haralick et al, 1992). An image with smaller CC indicates larger shape or cover changes in the cloud field making CMVs less accurate and violating the assumption of a ‘frozen’ cloud field. Reduced forecast accuracy would result.
AVGKT	$\sum_{i=1}^n p(kt_i)kt_i$	Spatially averaged cloud transmission.
Std	$\sqrt{\sum_{i=1}^n p(kt_i)(kt_i - \langle kt_i \rangle)^2}$	Average contrast of an image (see Fig. 3). For the same Cf an image with larger std would be more difficult to forecast.
Entropy	$\sum_{i=1}^n p(kt_i) \log_2 p(kt_i)$	Randomness of an image (see Fig. 3). For the same std an image with larger Entropy would be more difficult to forecast.
Uniformity	$\sum_{i=1}^n p(kt_i)$	Uniformity in image pattern (see Fig. 3). For the same Cf an image with smaller Uniformity would be more difficult to forecast.

Std:	0.19	0.19
Entropy:	0.134	0.07
Uniformity:	0.0122	0.069

**Figure 3.** Illustration of two different kt (colorbar; blue: thick clouds, red: clear) patterns. Both (2000 x 2000 km) images have the same average contrast (std) but different entropy and uniformity. The high entropy kt image (a) shows a random cloud field, while the low entropy kt image (b) shows a clear sky with a two well defined clouds.

110

### 111 3.3 Multivariate linear regression

112 To find out the important determinants of forecast error, a multivariate linear regression  
113 analysis of forecast error versus different combinations of features is performed as in

$$114 y = \beta_0 + \beta_1 x_1 + \dots + \beta_i x_i + \epsilon. \quad (1)$$

114

115  $y$  and  $x_i$  represents the RMSE of the forecast and features at a specific forecast hour respectively,  $\beta_i$  is  
116 the fit coefficient solved for in the regression analysis, and  $\epsilon$  is the error term representing the mismatch  
117 between the linear model and the observations. The coefficient of determination ( $R^2$ ) quantifies the  
118 goodness of fit and is defined as the ratio of the variance of the regression model and the variance of  
119 the observations:

$$120 R^2 = 1 - \frac{\sum_{i=1}^m (y_i - \hat{y}_i)^2}{\sum_{i=1}^m (y_i - \bar{y})^2} \times 100\% \quad (2)$$

120

121 where  $\hat{y}_i$  is the mean modeled  $y$  (Eq. 1) and  $\bar{y}$  is the mean measured  $y$ . The regression is fit to the  
122 training data and the results section shows results for an application to the test data (out of sample  
123 statistics).

### 124 3.4 Analog scheme

125 To address the limitations of the multivariable linear regression model, an artificial intelligence  
126 (AI) method called analog method is also used to estimate the forecast error. The analog of a forecast  
127 for a given location and time is defined as a past prediction that matches selected features of the  
128 current forecast. Analyzing historical forecasts errors for the analogs, forecast error can be inferred  
129 (DelleMonache et al. 2011).

130 The search for analog forecasts is controlled by a K-nearest neighborhood (KNN) algorithm  
131 consisting of a weighted normalized Euclidean distance metric ( $\|E\|$ ) that ranks past predictions by how  
132 similar they are to the current forecast

$$133 \|E\| = \sqrt{\sum_{i=1}^N \frac{(F_i - A_i)^2}{\sigma_i}}, \quad (3)$$

134 where  $F_i$  is the current forecast feature value;  $A_i$  is the feature value in an analog,  $N$  is the number of  
135 features,  $\sigma_i$  is the standard deviation of each feature in the training dataset respectively.

136 K analogs (K = 10 here) with the shortest Euclidean distance are then used to predict the error of  
137 the current forecast. A weighted average of the analog errors is computed as

$$138 AN = \sum_{i=1}^K \gamma_i E_i, \quad (4)$$

137 where AN is the weighted average error,  $E_i$  is the analog distance in (3), and  $\gamma_i$  is a weight that is  
138 inversely proportional to the distance of the analog from the forecast,

$$\gamma_i = \frac{1}{\sum_i^K \|E_i\|}. \quad (5)$$

139 Therefore, a higher weight will be assigned to the analog with the shortest distance from the current  
140 forecast.

## 141 **4. Results**

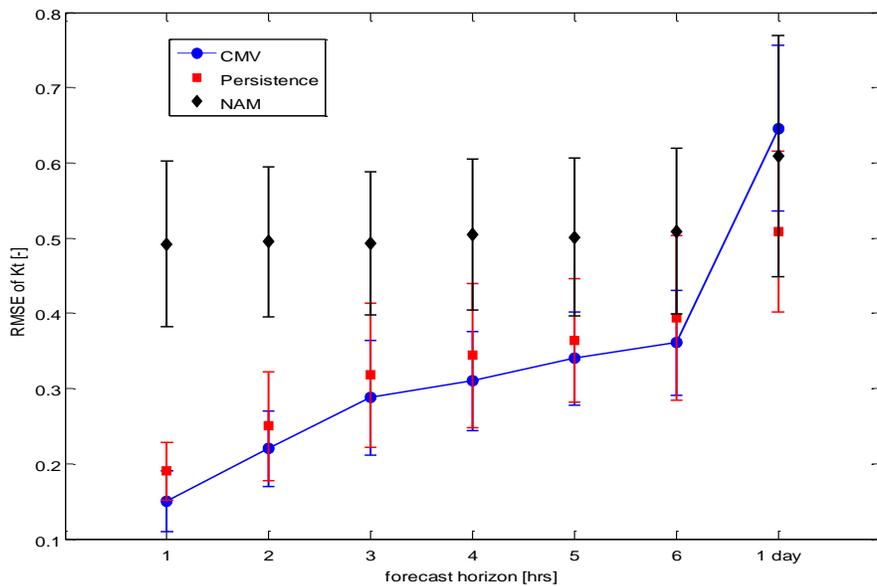

### 142 **4.1 Forecast performance of different methods**

143 The performance of CMV forecast is compared to the NAM forecast and basic persistence  
144 forecast that equates future with current weather condition, i.e. the current kt satellite image is  
145 assumed to persist. Forecasts are validated against the truth CLAVR-x kt image. Choosing satellite data  
146 as a validation source may artificially increase the NWP and decrease the satellite error, since identical  
147 (satellite) and different (NWP) methods are used to determine kt. Comparing forecast results to  
148 (independent) ground irradiance measurements would be preferable, but measurement sites are not  
149 available at our oceanic site and would also be very sparse over land. The root mean square error  
150 between the forecast and truth image is given as

$$RMSE = \sqrt{\frac{\sum_{i=1}^n (kt_f - kt_t)^2}{n}}, \quad (6)$$

151 where  $kt_f$  is the forecast kt,  $kt_t$  is the truth kt, and  $n$  is the number of pixels in an image.

152 Figure 4 shows the RMSE of kt at different forecast horizons for each forecast model. The NAM  
153 forecast error is shown to vary weakly with forecast horizon, which confirmed our earlier assumption.  
154 The CMV forecast error increases with increasing forecast horizon as expected. The persistence forecast  
155 errors are slightly larger than CMV forecast errors up to a 6 hours forecast horizon. The cross-over time  
156 between satellite CMV and NAM forecast is found to be in between forecast horizons of 6 hours and 1  
157 day, which is longer than in Perez et al. (2010) probably because Perez used ground measurements for  
158 validation.

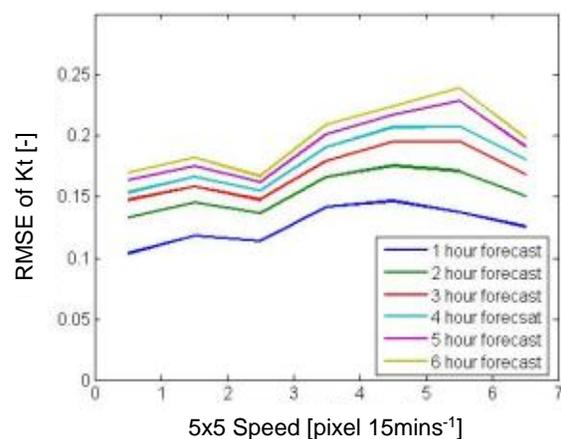

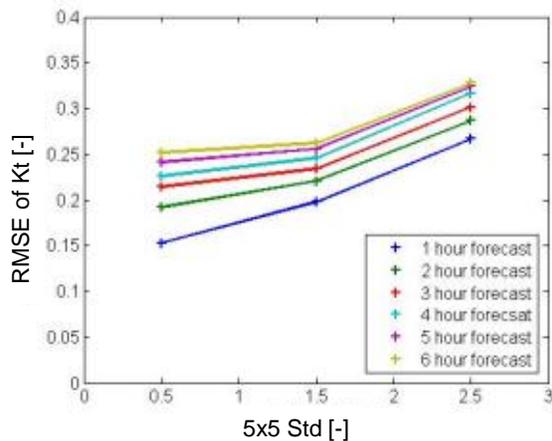

**Figure 4.** RMSE of kt as a function of forecast horizon for each forecast model. Error bars show the standard deviation of the RMSE. Note the jump from 6 hours to 1 day on the x axis.

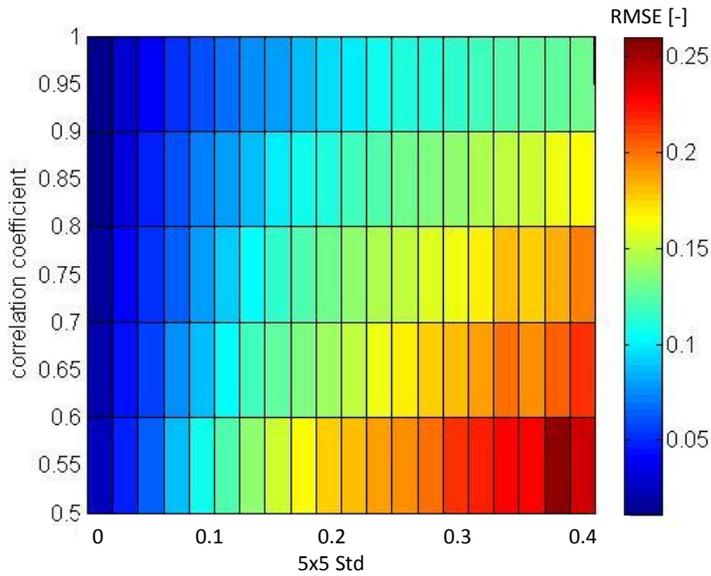

159

#### 160 4.2 Satellite forecast RMSE versus kt standard deviation, cloud speed, and 161 cross-correlation coefficient

162 To motivate the analysis in Section 4.3., dependencies of RMSE on a few features are shown in  
163 Figs. 5 and 6. The features are computed over 20x20 km (5x5 pixels) rather than the whole region  
164 described in section 3.2. Figure 5 shows that RMSE increases with increasing std for all forecast horizons.  
165 While RMSE also increases with increasing cloud speed, the increase is smaller ( $\sim 0.04$ ) than for the std  
166 ( $\sim 0.1$ ). Dependencies between the RMSE and a combination of two features are examined in Fig. 6;  
167 RMSE increases with increasing std and decreasing CC. The sensitivity of RMSE to CC increases with std.  
168 The  $R^2$  of RMSE vs std, RMSE vs speed, and RMSE vs std and CC for the 1 hour forecast is 36%, 15.8%,  
169 and 50.7% respectively.

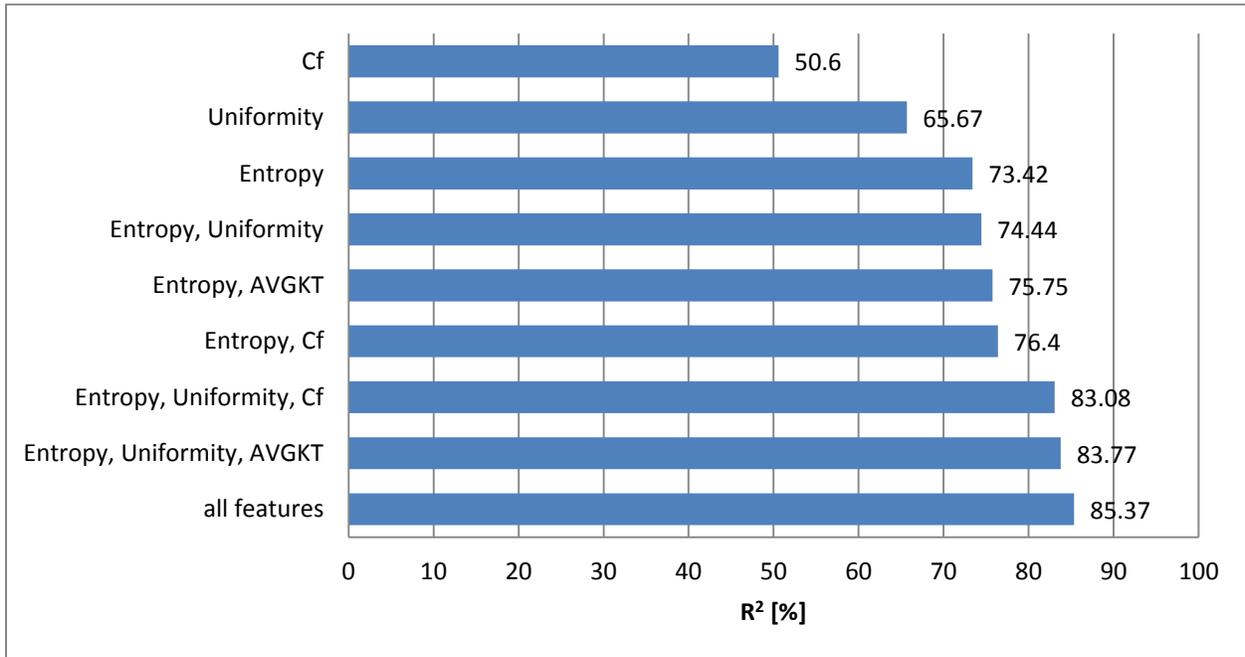

**Figure 5.** RMSE of kt as a function of std (left) and cloud speed (right) with different forecast horizons (colors).

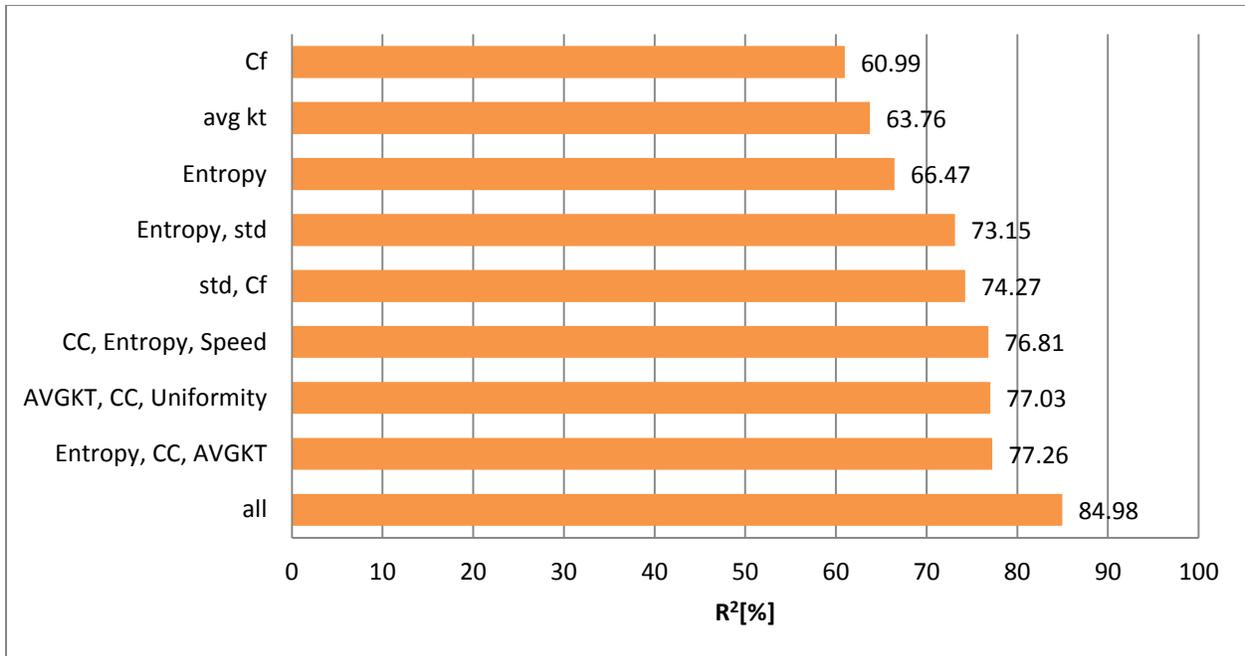

**Figure 6.** RMSE of kt (colorbar) as a function of std and CC for the 1<sup>st</sup> hour of CMV forecast.

170

### 4.3 Multivariate linear regression for satellite forecast RMSE

**Figure 7.** Coefficient of determination ( $R^2$ ) for different combination of features for the 1<sup>st</sup> hour (top) and the 5<sup>th</sup> hour of CMV forecast (bottom).

171 Figure 7 shows the coefficient of determination ( $R^2$ ) for several multivariate linear models (Eq. 1)  
 172 at different forecast horizons, each representing a different combination of features.  $R^2$  describes the  
 173 goodness of multivariate linear fit of RMSE. For the first forecast hour RMSE modeled with a single  
 174 feature, the satellite forecast RMSE is most correlated to Entropy ( $R^2=73.4\%$ ), followed by Uniformity  
 175 ( $R^2=65.7\%$ ). For two features, the highest correlated combination of features is Entropy and cloud  
 176 fraction with a 3% increase ( $R^2=76.4\%$ ) compared to the single feature using Entropy.  $R^2$  further  
 177 increases to 83% with a combination of Entropy, Uniformity and Cf or AVGKT. Adding extra variables  
 178 only slightly increases  $R^2$  to 85.4%. The  $R^2$  for single and double feature model has a similar trend for  
 179 forecast horizons of 1-3 hours. While cloud speed replaces Cf or AVGKT in triple variable models to  
 180 become the highest correlated combination, the difference in  $R^2$  is not significant. Entropy and  
 181 Uniformity are the most important features for 1-3 hour forecasts.

182 At the fourth to sixth hour of forecast, the combination of important features changes (Fig. 7  
 183 bottom). Entropy is still the feature with the largest  $R^2$ . The combination of CC, AVGKT, and Entropy or  
 184 Uniformity is found to have the highest correlation. Since entropy and uniformity are correlated and  
 185 cloud fraction is correlated to AVGKT, the main difference between the 1-3 hours and 4-6 hours models  
 186 is that CC has a larger impact on the forecast RMSE for longer (> 3 hours) forecast horizon.

187 The multivariate regression analysis suggests that Entropy (i.e. the randomness of the kt field,  
 188 Fig. 3) is the primary predictor of CMV forecast RMSE. A high randomness typically indicates that the  
 189 cloud pattern is made of many small scale clouds or clouds with high spatial variability of optical  
 190 thickness. Since smaller scale clouds tend to have a smaller 'half-life' than large clouds, the assumption  
 191 of a 'frozen' cloud field in the CMV method is violated, resulting in larger forecast error.

192 **4.4 Predicting CMV versus NAM forecast performance**

193 To demonstrate the performance of both predictive models, forecasts for May 25<sup>th</sup> - June 25<sup>th</sup>,  
 194 2012 are analyzed using April 24 – May 24, 2012 as the training period. The RMSE predicted by the  
 195 linear regression method in Eq. 1 and the weighted analog in Eq. 4 are validated against the truth RMSE.  
 196 The relative RMSE (rRMSE) of each model is computed as

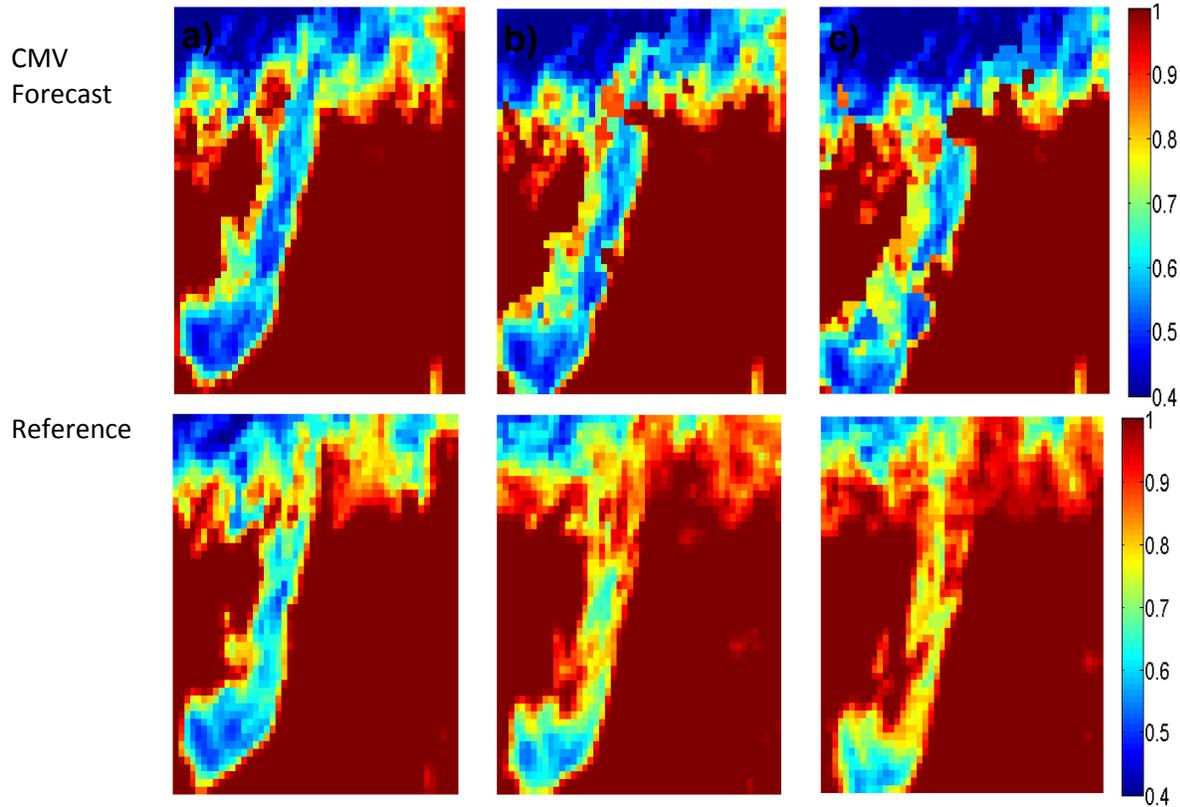

$$rRMSE_{model} = \frac{1}{RMSE_{mean}} \sqrt{\frac{\sum_{i=1}^n (RMSE_{predicted} - RMSE_{truth})^2}{n}} \times 100\% \quad (7)$$

197 where  $RMSE_{mean}$  is the mean of the truth RMSE.

198 To compare the predictability of errors of different forecasts, the relative performance (RP) is used:

$$RP_{NAM,i} = \frac{RMSE_{NAM,i}}{RMSE_{CMV,i}}, \quad (8)$$

199 where  $i$  indicates forecast horizon. The idea of RP is similar to the cross-over time mentioned earlier. RP  
 200 describes the relative performance of two models in terms of RMSE at a particular forecast horizon:  $RP <$   
 201  $1$  indicates that CMV performs better than the NAM forecast, and vice versa. Under certain conditions, a  
 202 cross-over time ( $RP = 1$ ) earlier than the one in Fig. 4 can be found (Fig. 8).

NAM  
Forecast

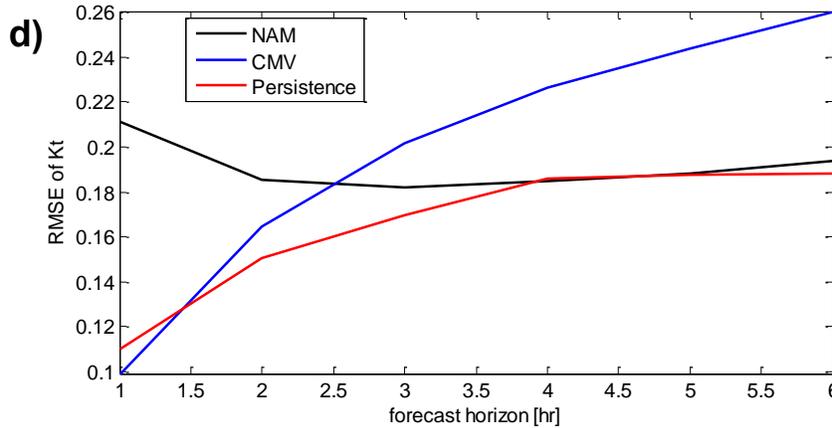

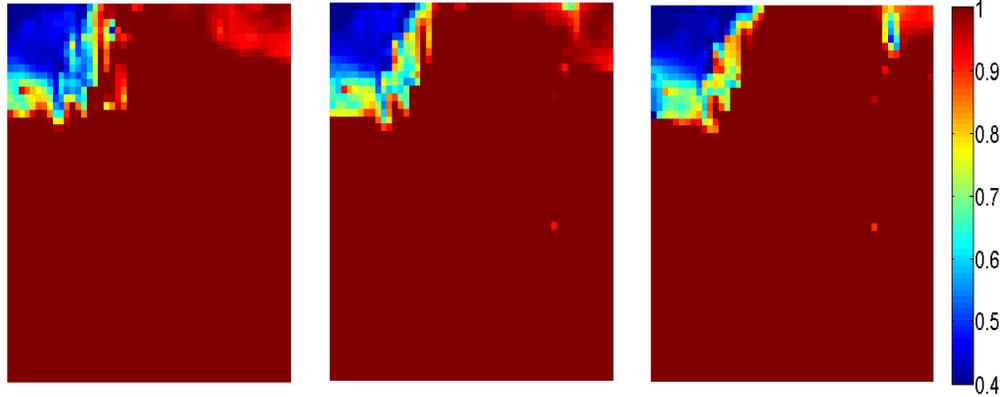

Figure 8. Images of kt at forecast horizons of (a) 1 hour (b) 2 hours (c) 3 hours for CMV and NAM forecasts and reference Kt on 27<sup>th</sup> May, 2012. The area shown is 234 × 470 km. In this case, the dissipation of clouds near the top and in the center and a phase-shift (i.e. change in cloud speed) of the north-south cloudy stripe led to a rapid increase in CMV forecast error and cross-over with the NAM forecast at 2.5 hours (d).

203 Table 2 shows a comparison of the performance of the multivariate regression and analog  
 204 method in predicting CMV forecast error and RP. The analog method is shown to outperform the  
 205 multivariate linear regression method with the best combination of features (largest  $R^2$ ) for both  
 206 predicting CMV forecast error and  $RP_{NAM}$ . The average rRMSE of predicting CMV forecast error is 14.4%  
 207 and 23.9% for analog and regression method respectively, while the average rRMSE of predicting  $RP_{NAM}$   
 208 is 27.6% and 31.7%. The errors of both methods are found to be independent of the forecast horizon.  
 209 Satellite image Uniformity is observed to be the most important feature for predicting the  $RP_{NAM}$ . The  
 210 impact of other features varies by forecast horizon.

**Table 2. Predicted CMV forecast error and RP with analog and multivariate linear regression model. Training data is from April 24 - May 24 and test data is May 25 – June 25, 2012.**

Forecast hour	Predicted CMV forecast error		Predicted $RP_{NAM}$	
	rRMSE <sub>analog</sub>	rRMSE <sub>regression</sub>	rRMSE <sub>analog</sub>	rRMSE <sub>regression</sub>
1	16.5%	21.4%	31.2%	37.3%
2	13.0%	28.6%	27.2%	30.6%
3	13.5%	19.7%	20.3%	27.2%
4	15.6%	23.5%	29.6%	31.0%
5	14.0%	23.2%	30.3%	35.1%
6	13.9%	27.1%	27.1%	29.0%

211 **5. Conclusions**

212 A technique for solar forecasting using satellite imagery with the ability to characterize and predict  
 213 the forecast error using multivariate linear regression and the analog model is presented. CMV solar  
 214 forecasts are computed using the cross-correlation algorithm applied pixel-by-pixel with CLAVR-x  
 215 processed GOES-15 cloud transmissivity for one month. On average, the RMSE is found to increase with  
 216 increasing forecast horizon for both persistence and CMV forecast and becoming large than NAM  
 217 forecast error (i.e. with a cross-over time) at forecast horizons between 6 hours and 1 day.

218 The dependence of forecast RMSE on different features is analyzed using multivariate linear  
 219 regression and analog models. Entropy is shown to contribute the most to the CMV forecast RMSE. The  
 220 rRMSE of predicting CMV forecast error is found to be 14.4% for the analog model and 23.9% for the  
 221 regression model. This indicates that the CMV model errors show a non-linear dependence on the  
 222 selected features that can be better captured by the analog method versus a linear regression.

223 The relative performance of NAM and satellite CMV models is also analyzed. Based on Fig. 4, RP  
 224 decreases from about 3.5 at the first forecast hour to 1.5 at the 6<sup>th</sup> forecast hour, on average. The cross-  
 225 over time (when CMV becomes less accurate than numerical weather prediction forecasts) is found to  
 226 be more than 6 hours, on average, but as early as 2 hours under certain conditions. The rRMSE of  
 227 predicting RP is shown to be 27.6% and 31.7% for analog and regression method respectively.  
 228 Consequently, both models have skill in informing forecasters at what forecast horizon a numerical  
 229 weather prediction forecast should start to be used instead of a satellite forecast.

230 With only two months of available CLAVR-x data, the model performance is limited by the data size  
 231 being used to train the models. Especially for the analog method a larger training data set increases the  
 232 chance to find similar analogs improving model accuracy.

233 Table 3 shows the pipeline of operational satellite CMV forecast and the processing time for each  
 234 step using a desktop computer. Using this strategy an operational forecast can be provided within less  
 235 than 25 minutes after satellite image capture.

**Table 3. Pipeline of CMV forecast and the processing time for each step**

Procedures	Processing time
Download and extract GOES15 data from CLARV-x	20 min
Compute cloud motion vectors	40 sec
Advect kt pixels and register forecast images out to 6 hours	20 sec
Predict errors and RP of CMV and NAM	90 sec
Total	23.5 min
